ARTICLE INFO

ABSTRACT

The mechanical, electrical and thermal properties as well as thermal expansion of Al/SiC/RHA (rice husk ash) monolayer and bilayer composite have been studied using the Taguchi method and analysis of variance (ANOVA). The parameter that most significantly affects the modulus of elasticity of Al/SiC/RHA bilayer composites is processing time, with contribution percentages of 68 and 27% calculated from stress-strain graphs and ultrasonic method, respectively. However, the factor which mostly affects bending strength, CTE value and electrical resistivity of composites is process temperature with contribution percentages of 32, 28, and 22%, respectively. The projected values for modulus of elasticity (170 GPa), bending strength (369 MPa), CTE ($8.9 \times 10^{-6}/°C$) and electrical resistivity (0.0019 Ω m) of Al/SiC/RHA composites are in excellent agreement with those obtained in the verification tests under the optimal conditions according to ANOVA.

1. Introduction

For some applications, composite materials are considered to be more suitable than conventional materials as they have desirable mechanical, thermal, electrical and wear properties. Among them, particulate reinforced composites (PMMCs) have attracted considerable attention due to their relatively low costs and inherent isotropic properties [1–3]. Metal matrix composites containing 25–60 vol % ceramic particulate in a high-strength matrix alloy have properties which are attractive for multifunctional electronic packaging, mirror substrates and support structures in optical systems, and components for inertial guidance systems [4–6]. The key requirements for this application are a high thermal conductivity and a coefficient of thermal expansion (CTE) similar to that of

materials commonly used in microelectronic systems [7]. Among the different composites that are nowadays being considered for these applications, Al/SiC composites with a high-volume fraction of particulate reinforcement are a suitable and versatile option due to outstanding physical properties of SiC particles (High thermal conductivity, low CTE value and electrical conductivity). Although the Infiltration of ceramic preforms by liquid metals has been typically applied for the processing of composite materials with high percentage of reinforcement [8,9], as a constitutive route, it offers the potential for the production of graded composite materials by variation of shape, size, and volume fraction of the reinforcement in each layer. Successful fabrication of bilayer graded Al/SiC/RHA composite by pressureless infiltration method has been reported elsewhere [10]. In addition to the outstanding properties of RHA in different sectors such as cement industry, electronics, catalyst supports and etc. [11,12], recently it is widely used in fabrication of hybrid metal matrix composite materials [13]. Although SiO_2 derived from rice husk is by nature non-wettable, embedment of amorphous and crystalline SiO_2-derived RHA into SiC substrates up to 20 wt% will not make the system non-wettable

by Al-Si-Mg alloys [14]. RHA act as an oxygen donator to form MgO and $MgAl_2O_4$ in the Al/SiC/RHA system and as a results fabrication of hybrid composite. Also, in presence of amorphous RHA the formation of deleterious phase of Al_4C_3 was eliminated. Significant increase in hardness of fabricated hybrid Al/SiC/RHA composite in comparison to the conventional Al/SiC composite were observed [10].

In the present work, the quantitative effect of processing parameters on the bending strength and modulus of elasticity as well as physical properties such as electrical resistivity, CTE value and thermal diffusivity of monolayer and bilayer Al/SiC/RHA composite are investigated. The optimum conditions for abovementioned mechanical and physical properties of composites are projected and the infiltration characteristics under optimum conditions are determined and verified.

2. Experimental procedure

Infiltration tests for composites of Al/SiC/RHA were conducted under the conditions shown in Table 1. The effect of various parameters on the mechanical and physical properties of composite were investigated using the Taguchi method for design of experiments [15]. Infiltration temperature, time, particle size, porosity, SiO_2 crystallinity and content in the bilayer preform were used as parameters of infiltration process. The fabrication method as well as fabrication conditions have been discussed in details elsewhere [10]. Table 2 show L27 Taguchi tables used for this study.

Specimens for microstructure analysis were mounted and polished using standard metallurgical procedures, and the analysis was done using X-ray diffraction (XRD), scanning electron microscopy (SEM) and energy dispersive X-rays (EDXs). The elastic modulus and bending strength of all fabricated monolayer and bilayer composites were determined using bend test bars of dimensions $2 \times 1.5 \times 25$ mm. The bending strength was measured in the four-point mode taking into account the compliance of the test system. The support distances were 10 mm and 20 mm. The elastic modulus was calculated from the first resonant frequency of the bar in accordance with ASTM C1161-13 [16].

Coefficient of thermal expansion (CTE), Electrical resistivity and thermal diffusivity of all fabricated composite were measured in this study. CTE values were measured by TMA 402 F1/F3 Hyperion®, a Thermomechanical Analyzer - Vertical Dilatometer. Samples were cut from the alloys and composite with the size of $3 \times 3 \times 2$ mm. Both crystalline and amorphous silica were heated up to 1000 °C, while the temperature of 300 °C was chosen for aluminum alloys and composites. All samples were heated up and cooled down with the rate of 20 °C/min under protective atmosphere of high purity nitrogen with the flow rate of 30 cm^3/min.

Electrical resistivity and conductivity were measured using four-point probe technique (Lucas Labs S-302 Four Point Probe) on

the flat faces of the samples. The measurement was conducted using direct current (DC) in order to avoid skin effects associated with AC current in the matrix and transient polarization phenomena in the ceramic component. To eliminate thermoelectric and capacity effects of the setup, the direction of the current was repeatedly reversed manually and the average of the absolute value of the two measured voltage drops was taken. The two values usually differed by less than 1% of their average. To avoid systematic errors, similar specimens were cut from the unreinforced matrix material and tested under the same conditions. The reliability of the measurements was assessed by measuring a sample 10 times

(including extraction and re-insertion of the specimen in the measurement rig); the variation of the data was found to be in the order of 0.1% of the mean value.

The thermal diffusivity (α) was measured by the laser flash method on square or disk samples of dimensions $8 \times 8 \times 1$ mm and 10×1 mm, respectively, using a Netzsch LFA 457 MicroFlash™ diffusivity apparatus. The surfaces of the samples were graphite coated to avoid direct transmission of the laser pulse through the specimen and to improve energy absorption. Measurements were done from room temperature up to 300 °C always in an argon atmosphere.

3. Results and discussions

The microstructures of the all fabricated Al/SiC/RHA bilayer composites studied in this work have previously been studied by scanning electron microscopy and X-ray diffraction [10]. Both layer of composite fabricated according to L2 configuration as well as microstructure of bilayer L17 are presented in Fig. 1a–c. SEM and XRD analyses confirmed that during pressureless infiltration of aluminum alloys into SiC/RHA porous preforms, RHA keeps its structure, and depending on the crystallinity of RHA (crystalline or amorphous), it acts as an oxygen donor to form $MgAl_2O_4$ and MgO. Moreover, it prevents formation of the deleterious phase, aluminum carbide in compliance with Le Chatelier's principle. Also, formation of AlN was intensified when high infiltration temperature (1300 °C) and long processing time (150 min) were used for fabrication of Al/SiC/RHA composites. As it can be seen in Fig. 1a and b, complete infiltration caused a microstructure free of defects such as porosity, cracks and inhomogeneity. Short infiltration time or low processing temperature as well as inappropriateness of preform architecture can cause incomplete infiltration in top layer of preform or free metal regions in the final microstructure of obtained composite (Fig. 1c).

3.1. Bending strength and modulus of elasticity (from bending test and ultrasonic method) of Al/SiC/RHA bilayer composites

Typical stress–strain curves recorded during the four-point bending test of bilayer and monolayer Al/SiC/RHA composites are shown in Fig. 2. Also, the value of modulus of elasticity calculated from both pulse-echo ultrasonic method and stress-strain curves as well as bending strength of both monolayers and bilayer composites, are presented in Table 3. As it can be seen from Fig. 2, the plastic deformation zone is disappeared due to brittle essence of ceramic particles and as a consequence MMCs with high percentage of ceramic reinforcements.

It is clear from Fig. 2 that except for L9-Al/SiC/RHA composite, each layer of bilayer composite, depend on the weight percentage of reinforcement and the position of layer (bottom or top) during pressureless infiltration process has different bending strength from another layer and bilayer composite. Also, it can be observed that L27 bilayer composite has the highest bending strength (334 MPa), followed by L25 (298 MPa) and L8 (271 MPa) composite. Considering the L27 Taguchi table, amorphous RHA was used in both L27 and L8 composite. High temperature and long process time (L25 and L27) cause complete formation of hard phases such as AlN and $MgAl_2O_4$ through the matrix. Also, L8 configuration provides the situation that high Mg alloy is in contact with amorphous RHA for a long procedure time. It causes formation of MgO in addition to $MgAl_2O_4$ and AlN in matrix.

In addition to chemical composition of composite, the reinforcement architecture could be other important factor which controls the crack nucleation and propagation through the layers. Load bearing layer of both L27 and L8-Al/SiC/RHA which have highest bending strength values, contains small size particle of SiC with almost low level of preform porosity. Since there is a good bonding between matrix and particle, the crack initiation site would be limited.

As it can be seen from Fig. 2 and Table 3, in general it can be said that those composite who their load bearing layer has higher bending strength than another layer, have higher total bending strength (Such as L27, L25, L13 and L2). Comparison between young's modulus data obtained by Pulse-Echo technique and from stress-strain curves shows that there is a negligible difference between the results obtained by these two methods. It can arise from difference between the tested areas in the samples. Probe in Pulse-Echo method covers an area of 0.78 cm^2 while bending sample fabricated according to configuration A of ASTM 1161 standard covers an area of 0.4 cm^2. The fracture micrographs of monolayer and bilayer L27 Al/SiC/RHA composite are presented in Fig. 3. It clearly shows that almost all the SiC particles on the fracture surfaces belong to the cracked particles rather than debonded ones and the most of particles run parallel to the fracture surfaces of the composites.

This mode of fracture indicates that the failure is dominantly caused by the SiC particles fracture and Al-matrix dimple rapture rather than by the interface debonding, which means that the interface bonding between Al-matrix and SiC reinforcement is significantly strong. Interface bonding as well as fine aluminum dimples and cleavage fragment of SiC particle can be seen clearly in Fig. 4.

Also, magnesium in the aluminum alloy can reduce the oxides present in the preform systems due to its high affinity for oxygen; thus, development of the magnesium aluminate spinel ($MgAl_2O_4$) during the processing is highly feasible (see Fig. 3). As it was reported before, reduction of SiO_2 by molten aluminum and magnesium occurs through extremely exothermic events. The spontaneity of this reaction through the whole range of temperatures fairly explains the presence of $MgAl_2O_4$ in mostly all

fabricated composites.

AlN fine needles can be observed in all examined fracture surface of Al/SiC/RHA composites. Aluminum nitride (AlN) may be produced through the direct reaction of molten aluminum and nitrogen gas according to [17]:

$$Al\ (l) + [N] \rightarrow AlN\ (s) \qquad \Delta G°_{1100} = -556.2\ \text{kJ/mol} \qquad (1)$$
However, due to the presence of magnesium in the system, AlN can be formed through the following reactions as well:

$$3Mg\ (g) + 2\ [N] \rightarrow Mg_3N_2\ (s) \qquad \Delta G°_{1100} = -945.5\ \text{kJ/mol} \qquad (2)$$

$$Mg_3N_2\ (s) + 2Al\ (l) \rightarrow 2AlN\ (s) + 3Mg\ (l) \qquad \Delta G°_{1100} = -166.3\ \text{kJ/mol} \qquad (3)$$

Reaction 2 implies the interaction of Mg in vapor phase with the flowing nitrogen in the process atmosphere. In order to take

	Bilayer	163.91	160.80	340

advantage of magnesium as a surfactant element and thus enhance the wetting of the ceramic reinforcement by liquid aluminum, it is highly desirable that reactions 2 and 3 take place. In this way, Mg is recycled to the melt [18]. Due to its low vaporization temperature as compared to that for aluminum at normal pressure, magnesium escapes from the melt during processing. Reactions 2 and 3 are strongly exothermic and although from the thermodynamics standpoint, nitridation of both, Mg and Al is highly feasible, according to the literature, kinetically the reaction for formation of Mg_3N_2 is much more favorable than that for AlN. In the present work, aluminum nitride was typically observed in the microstructure of the composite nearby the metal/ceramic interface in the form of needles or fibers oriented randomly, as illustrated in Fig. 5.

Fig. 6 shows the fracture surface of L3-Al/SiC/RHA composite. As it can be seen, there exist alloy free zones in fracture surface of both layers of fabricated composite. It can be attributed to the poor wettability of SiC/20 wt% RHA mixture with low mg alloy at low processing temperature. Also, the nucleus of AlN in both layers were observed on SiC particles, indicating that the situation provided by configuration L3 were not adequate enough to intensify the growth of AlN fibers or needles.

Analysis of variance (ANOVA) was performed on the data in order to identify the effect of each parameter and each interaction on the modulus of elasticity and bending strength of the graded composites. Results of the pooled ANOVA for the modulus of elasticity are shown in Table 4. This table indicates that, at the levels studied, the parameter that affects the bending strength of graded composites most significantly is temperature of infiltration process followed by interaction of time and temperature of process and chemical composition of alloy. Their relative contribution to the variance in the modulus of elasticity values are 32, 14 and 13%, respectively. Temperature and time of process can define the amount of matrix free regions and consequently the retained porosity content of fabricated composite.

Considering the parameters and levels of designed experiment, the maximum bending strength can be obtained by using the process parameters shown in Table 5. When using these process parameters, the projected bending strength is 363 ± 5 MPa.

Results of the pooled ANOVA for the modulus of elasticity calculated from echo-pulse ultrasonic method are shown in Table 6. This table indicates that, at the levels studied, the parameter that affects the modulus of elasticity of graded composites most significantly is time of process. Its relative contribution to the variance in the modulus of elasticity values is 27%. It is expected that, due to capillary effects, this parameter has a significant contribution to the modulus of elasticity values because an inadequate time may restrict the elevation of the liquid metal up to the interface formed by both preforms and end of the preforms and causes high percentage of porosity content. The residual porosity in the composites negatively affects the wave velocity because wave propagation is higher in solids than in air. SiO_2 crystallinity, on the other hand has a direct effect on the level of in-situ formed phases in the final composite and as a result can affect the density of fabricated composites and their modulus of elasticity values. Preform porosity, also affects the modulus of elasticity of the composites notably. Its relative contribution to the modulus of elasticity is about 13%. It is expected that the original porosity designed in the preform has a relatively high effect on the composite's modulus of elasticity since this porosity becomes infiltrated with the less elastic component of the composite, i.e. aluminum alloy. Consequently, the higher the preform porosity levels, the higher the aluminum alloy content of the composite, and the lower the modulus of elasticity of the composite. The percent contribution due to the error term in this ANOVA is 1%. This indicates that no important factors were omitted in the design of the experiment, and measurement errors were trivial.

Considering only the parameters and interactions included in Table 1 in the ranges tested, the maximum modulus of elasticity can be obtained by using the process parameters shown in Table 7. When using these process parameters, the projected modulus of elasticity is 169 ± 9 GPa.

Table 8 lists the results of the pooled ANOVA for the modulus of

Fig. 4. Good bonding between SiC particles and matrix alloy.

elasticity obtained from stress-stress curves. Table 8 indicates that, at the levels studied, the parameter that affects the modulus of

elasticity of graded composites most significantly is time of process. Its relative contribution to the variance in the modulus of elasticity
**Fig. 5.** Presence of AlN needles in fracture surface of Al/SiC/RHA composite.

Fig. 6. The fracture micrographs of monolayer and bilayer L3 - Al/SiC/RHA composites.

values is 27%.

Considering only the parameters and interactions included in Table 1 in the ranges tested, the maximum modulus of elasticity can be obtained by using the process parameters shown in Table 9. When using these process parameters, the projected modulus of elasticity is 173 ± 6 GPa.

Since both sets of processing parameters — obtained through ANOVA — for maximum bending strength and modulus of elasticity obtained from both methods of pulse-echo ultrasonic method and stress-strain curves are the same, they were validated in one single verification test under the experimental conditions established in Tables 5, 7 and 9. The fact that all optimum processing parameter

sets obtained in separate ANOVA tables are the same, provides an increased level of confidence in the obtained results. The measured modulus of elasticity calculated by pulse-echo ultrasonic method and from stress-strain curve are 165 and 170 GPa, respectively, and the determined bending strength 369 MPa. These results are in good agreement with the projected values (169 ± 9, 173 ± 6 GPa and 363 ± 5 MPa, respectively).

3.2. Thermomechanical analyzes

3.2.1. Aluminum alloys and rice husk ash

The dimensional and mechanical stability of materials is of paramount importance to their use in the everyday world where they may encounter a wide variation in temperature through design or by accident. Fig. 7 shows thermal strain response curve obtained during heating and cooling of amorphous silica and crystalline silica. In crystalline silica, a considerable increase and decrease were observed during heating and cooling of sample, respectively. It can be attributed to the phase transformation of cristobalite $\alpha \rightarrow \beta$. This behavior is in good agreement with previous works [19,20]. Also, this phase transformation is confirmed by DTA results presented in Fig. 8. As it can be seen, a sharp increase and decrease in both heating and cooling curves of amorphous

silica were observed at temperature of about 200 °C. According to Huang and Kieffer [21], thermomechanical anomalies of amorphous silica are due to the localized reversible structural transitions, which are facilitated by modes of atomic displacement similar to the ones underlying the $\alpha \rightarrow \beta$ cristobalite phase transformations in crystalline silica, i.e., spontaneous Si-O-Si bond rotations. This phenomenon also is confirmed by DTA and TG results obtained from heating of amorphous rice husk ash (Fig. 8). It was also reported that the thermal expansion of amorphous silica is much lower than that of silicon. In contrast, the thermal expansion of crystalline silica is higher than that of silicon [22].

Fig. 9 shows thermal strain response curve obtained during the four cycles of heating and cooling between 25 °C and 250 °C on pure aluminum, alloy 1 and 2. Also CTE values of alloys in different temperature for each heating curves are presented in Fig. 9. As it can be seen, alloying causes a decrease in the CTE value of pure aluminum. Higher level of Mg in Alloy 2 increase the percentage of Mg_2Si intermetallic (CTE: 7.5×10^{-6}/°C) in the alloy and as a consequence more reduction in CTE value of alloy 2 in comparison to alloy 1. CTE of Al-matrix (aluminum alloys) increased with the increasing temperature. The average distance between α (Al) atoms in crystal lattice was enlarged by the intensified lattice vibration, which impaired the metallic bonds and elastic modulus and finally

resulted in the growth of CTE. However, it was reported that CTE of Al-Mg-Si alloys slightly fell down when temperature was higher than 400 °C. This deregulation could be explained by the increasing solubility of silicon and magnesium in α (Al) crystal at high temperatures, which reduced the lattice constant of α (Al) crystal [23]. The thermal response curves illustrate how the material expands and contracts in response to fluctuations in the operating temperature. Three parameters commonly used to characterize these curves are shown also in Fig. 9. The ε^p is used to quantify the residual plastic strain, $\Delta\varepsilon^t$ is used to quantify the largest vertical (at a given temperature) difference between the cooling and heating curves, and ε^c is the cyclic strain which gives information equivalent

to that provided by the CTE. The degree of thermal damage and stability can be evaluated from ε^p, $\Delta\varepsilon^t$ and ε^c.

The thermal response results of all specimens from the heating of the first cycle to the cooling of the forth cycle are shown in Table 10. The results show that the ε^p and ε^c of all samples decreased as the percentage of alloying elements increased, indicating that Si and Mg addition to the aluminum is beneficial to the dimensional stability of Al-Mg-Si alloy.

3.2.2. Al/SiC/RHA bilayer composite

CTE values obtained from thermal strain response curves of all fabricated Al/SiC/RHA composites are presented in Fig. 10. It is clear that addition of reinforcing phases to Al-Si-Mg alloys leads to a dramatic decrease in the value of CTE. The thermal response results of all fabricated composites from the heating of the first cycle to cooling of the forth cycle are shown in Table 11. As it can be seen, lowest parameters (ε^p, ε^c and $\Delta\varepsilon^t$) are belonged to the samples with low CTE values. Thermal strain can be attributed to thermal stress. During heating process, the thermal stress exhibit as tensile stress on the ceramic reinforcement and compressive stress on the metal matrix. On the contrary, during cooling process the thermal residual stresses exhibit as compressive stress on ceramic reinforcement and tensile stress on the metal matrix. Assumed that both elastic and plastic deformation form as the thermal strain response,

Fig. 9. Thermal strain response curve and CTE values obtained during the four cycles of heating and cooling between 25 °C and 250 °C on pure aluminum, alloy 1 and 2.

Table 10
Thermal response parameters and CTE of pure aluminum and Al-Mg-Si alloys with different content of Mg.

Materials	ε^p	ε^c	$\Delta\varepsilon^t$	CTE (10^{-6}/°C)
Pure Al	0.00087	0.0030	0.0054	28.17
Alloy 1	0.00068	0.0050	0.0038	25.29
Alloy 2	0.00062	0.0048	0.0030	24.07

the elastic displacements are recovered during cooling. Therefore, higher thermal stress can lead to the generation of strain hysteresis between the heating and cooling cycles and to the retention of residual strain as the result of the plastic deformation or yielding of materials [24]. The thermal hysteresis behavior can be explained in terms of the weak interface between reinforcements and matrix or large internal stress released in the composites. Once the composite had undergone significant plastic deformation during the heating process, the lack of bonding force could not produce large enough stress to deform the matrix back to its original size upon cooling.

It is generally known that thermal stress results from thermal expansion incompatibility in materials during the temperature changes. Such a stress can induce the thermal strain in the specimens during thermal cycling. High thermal stress can lead to the

generation of strain hysteresis between the heating and cooling cycles and to the retention of residual strain. The residual strain is the result of the plastic deformation or yielding of the materials. The origins of thermal stress include thermomechanical mismatch between two materials, non-uniform temperature distribution in a material and thermal expansion anisotropy in a single phase material [25]. In the case of MMCs, thermal stress is known to arise from the difference of the CTE values between the matrix and ceramic reinforcing phase.

Pooled ANOVA results for the CTE values of Al/SiC/RHA graded composite are listed in Table 12. It shows that at the levels studied, the parameter that affects the CTE values of composite most significantly is the temperature of infiltration process. Its relative contribution to the variance in composite CTE value is 28%. Time of infiltration process and interaction of time and temperature have the same effect on the CTE values of composite with the contribution percentage of 16%. As it was discussed before temperature of process can define the amount of new ceramic phases in final structure of composite. From the data, which are presented in Table 12 it can be concluded that the composites which were made in higher processing temperature have lower CTE values than those were fabricated in lower temperature.

Considering experiment parameters and levels designed for this

Fig. 10. CTE values obtained during the four cycles of heating and cooling between 25 °C and 250 °C on Al/SiC/RHA composites.

study, the minimum CTE value can be obtained by using the process parameters shown in Table 13. When using these process parameters, the projected CTE value is $8.6 \pm 1.2 \times 10^{-6}/°C$.

The verification test has been done according to the optimum parameters proposed by ANOVA for minimum CTE value. The measured CTE was $8.9 \pm 0.8 \times 10^{-6}/°C$. This result is in good

agreement with the projected values ($8.6 \pm 1.2 \times 10^{-6}$/°C).

3.3. Electrical resistivity

Electrical resistivity and conductivity were measured using four-point probe technique on the flat faces of the samples. Fig. 11 shows those values for pure aluminum, alloy 1 and alloy 2. As it can be seen alloying with Mg and Si cause a reduction in electrical conductivity of pure aluminum. Reduced conductivity in solid solutions is explained as follows. Atoms of the two metals concerned, having a certain resemblance, enter side by side into the same crystal lattice. Hence, a mixed crystal is formed. In this new distorted structure, the electrons find difficulty in moving from atom to atom. Thus the resistance of the alloy becomes greater [26]. Furthermore, this reduction was intensified by increasing Mg content in alloy 2 due to formation of intermetallic phase of Mg$_2$Si (electrical conductivity of Mg$_2$Si = $14 \times 10^2 \ \Omega^{-1}$m^{-1}) [27].

Fig. 12 shows the electrical resistivity and conductivity of all monolayer and bilayer Al/SiC/RHA fabricated composites. As it can be seen among Al/SiC/RHA bilayer fabricated composites, L27 composite has the highest resistivity ($2.02 \times 10^{-3} \ \Omega$ m) and lowest conductivity ($4.95 \times 10^2 \ \Omega^{-1}$ m^{-1}) values. Since in all fabricated composites, in addition to the main constituents, secondary phases (MgO, MgAl$_2$O$_4$, AlN, Al$_4$C$_3$, etc.) are formed, their electrical properties can affect the final properties of composite positively or negatively.

Aluminum nitride (AlN) ceramics are currently of interest because they combine a high thermal conductivity (175 W/mK) with a high electrical resistance ($>10^{12} \ \Omega$ m) at room temperature. As it was reported before [10], formation of AlN in Al/SiC/RHA composites were confirmed by XRD and EDS. The amount of AlN phase in the final fabricated composite is controlled by different parameters, such as Mg concentration of alloy, time and temperature of infiltration process etc. In XRD pattern of L27-Al/SiC/RHA composite, intensity of AlN peaks are stronger than those of other

composites [10]. Therefore, high electrical resistivity of L27-Al/SiC/RHA composite could be attributed to the formation of high amount of AlN during fabrication process.

Besides AlN, other ceramic phase that can have direct effect on electrical properties of Al/SiC/RHA composite is MgAl$_2$O$_4$. MgAl$_2$O$_4$ exhibits a unique combination of properties such as a low thermal conductivity, a low coefficient of thermal expansion, good thermal shock resistance, a low dielectric constant and high electric resistivity ($0.83 \times 10^{-2} \ \Omega$ m) [28]. Like AlN, formation of MgAl$_2$O$_4$ is highly depended to the temperature of process and crystallinity of RHA as an oxygen donor during the fabrication processing. L27 configuration provides a condition with high processing temperature for transformation of MgO phase to MgAl$_2$O$_4$ and also amorphous RHA with high reactivity and suitable structure for oxygen donation.

Fig. 12. Electrical a) conductivity and, b) resistivity of monolayer and bilayer Al/SiC/RHA fabricated composites.

Analysis of variance (ANOVA) was performed on the data in order to identify the effect of each parameter on the electrical resistivity of the graded composites. Results of the pooled ANOVA for the electrical resistivity are shown in Table 14. This table indicates that, at the levels studied, the parameter that affects the electrical resistivity of graded composites most significantly is infiltration process temperature followed by SiO_2 crystallinity. Their relative contribution to the variance in the electrical resistivity values are 22 and 16%, respectively. The reason of proposing temperature as a main governing parameter could be its important role in formation of new ceramic phases in composite. In-situ formation of phases like spinel, magnesium oxide and aluminum nitride can reduce the electrical conductivity of matrix due to consumption of aluminum alloys during their formation.

Considering the tested parameters and levels, the maximum electrical resistivity can be obtained by using the process parameters shown in Table 15. When using these process parameters, the projected electrical resistivity is 0.0017 ± 0.0008 Ω m.

The verification test has been done according to the optimum parameters proposed by ANOVA for maximum electrical resistivity. The measured electrical resistivity was 0.0019 ± 0.0003 Ω m. This result is in good agreement with the projected values (0.0017 ± 0.0008 Ω m).

3.4. Thermal diffusivity

Thermal diffusivity (α with the unit mm^2/s) is a material-specific property for characterizing unsteady heat conduction. This value describes how quickly a material reacts to a change in temperature. Thermal diffusivity controls the time rate of temperature change as heat passes through a material. It is a measure of the rate at which a body with a nonuniform temperature reaches a state of thermal equilibrium. Under real conditions or in specific applications, temperatures are not held constant, which means that thermal transfer through the material decreases the thermal gradient. Under such conditions, thermal diffusivity becomes important.

Fig. 13 (a) shows the thermal diffusivity of the main starting materials in this investigation [29–31]. For non-metallic solids, the

heat transfer is view as being transferred via lattice vibration, as atoms vibrating more energetically at one part of a solid transfer that energy to less energetic neighboring atoms. This can be enhanced by cooperative motion in the form of propagating lattice waves, which in the quantum limit are quantized as phonons. As it was expected both fabricated alloys have less thermal diffusivity values than pure aluminum. Alloying causes distortion of structure which makes the movement of electrons difficult through the atoms [26]. Thus, diffusion of electrons decreases with increasing the content of alloying elements.

Fig. 13 (a) shows the temperature-dependence of thermal diffusivity of SiC, the roughly T^{-1}-dependence diffusivity for SiC, suggesting a dominant phonon conduction behavior, which resembles most polycrystalline materials [32]. As it can be seen, the difference between values became smaller at elevated temperatures, e.g. ~12% at 800 °C. This difference in thermal diffusivity may be the result of a number of factors such as impurity, grain size, crystal boundary, etc. [33]. Charvat and Kingery [34], reported that the presence of impurity causes a considerable reduction in

thermal conduction properties, even when contamination is below 1%. As a matter of fact, impurities usually have a significant effect on the thermal conduction of highly pure polycrystalline, as well as single-crystal, solids [35].

Thermal diffusivity values for all fabricated Al/SiC/RHA over the time are presented in Fig. 13(b). As it can be seen fabricated composites according to the configurations 3, 8 and 9 have the highest thermal diffusivity values, respectively. Considering the fabrication parameters of composites with highest thermal diffusivity postulate that a combination of low reactive materials and use of preform with higher amount of SiC can results in fabrication of composite with high thermal diffusivity. L3 composite benefits from low Mg alloys and Crystal type II silica which both has a less reactivity in comparison to High Mg alloy and amorphous or Crystal type 1, respectively. Therefore, the percentage of aluminum matrix in final composite will be remained high.

On the other hand, all these three-mentioned composites were fabricated in low temperature which causes to less reaction between the components. L8 composite although is fabricated from High Mg allot and amorphous silica, its unique SiC architecture (Combination of fine and large SiC particles with high thermal diffusivity) makes it a composite with high value of thermal diffusivity. Also, the content of silica is 10 wt% of reinforcement which means the final composite is reinforced mainly with SiC particles.

4. Conclusions

Based on the results and carried out discussion, within the framework of the experimental design, with the parameters and levels defined for this project, the following conclusions can be drawn:

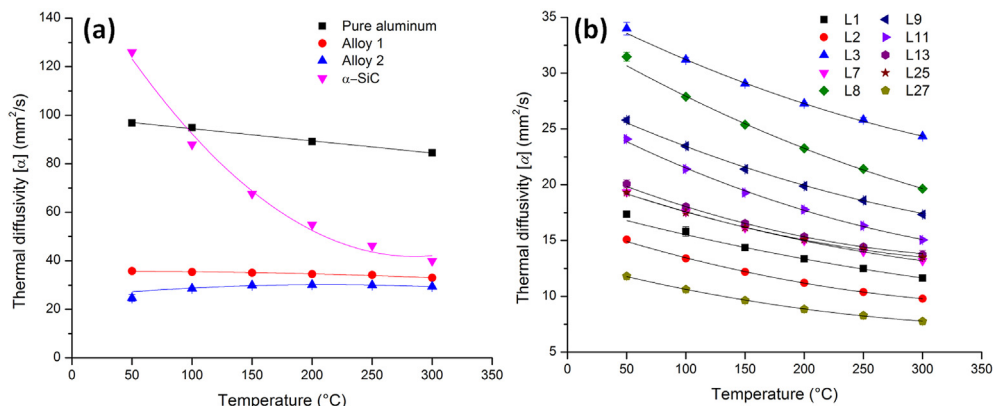

Fig. 13. Thermal diffusivity of (a) pure aluminum [29,30], α-SiC [31], alloy 1 (low Mg) and 2 (high Mg), and (b) Al/SiC/RHA bilayer fabricated composites at different temperatures.

1. The parameter that most significantly affects the modulus of elasticity of Al/SiC/RHA bilayer composites is processing time, with contribution percentages of 68 and 27% calculated from stress-strain graphs and ultrasonic method, respectively. However, the factor which mostly affects bending strength, CTE value and electrical resistivity of composites is process temperature with contribution percentages of 32, 28, and 22%, respectively. It is to visualize that temperature can affect all possible reactions which may occur during the process and that formation of each phase can substantially change the final properties of the composite. In the lower temperature range, formation of MgO is more possible while at higher temperatures, MgO can be replaced by $MgAl_2O_4$. Also, formation of AlN can be intensified by increasing the process temperature and time which can produce a composite with low CTE value and high electrical resistivity (L27).

2. The projected values for modulus of elasticity (170 GPa), porosity content (2.0%), bending strength (369 MPa), CTE ($8.9 \times 10^{-6}/°C$) and electrical resistivity (0.0019 Ω m) of Al/SiC/RHA composites are in excellent agreement with those obtained in the verification tests under the optimal conditions according to ANOVA. The differences between the corresponding values obtained in verification tests and those of projected values, for bending strength, porosity content, modulus of elasticity (obtained from both methods) and CTE are below 5%, while that for electrical resistivity is 11%.

3. Al/SiC/RHA composites with electrical resistivity (2.02×10^{-3} Ω m) in the range of semiconductor materials (10^{-10} Ω m $< \sigma < 10$ Ω m) can be produced by processing porous preforms of 10 wt% amorphous silica (L27) with the Al-13Si-9Mg alloy at 1300 °C for 150 min.
